

## TETANUS: A REVIEW

Raymond Towey, Department of Anaesthesia, St.Mary's Hospital Lacor, Gulu, Uganda

Tetanus remains an important cause of death worldwide and is associated with a high mortality, particularly in the developing world. With modern intensive care management, death from acute respiratory failure should be prevented, but cardiovascular complications as a result of autonomic instability and other causes of death remain.<sup>1</sup> In this article, the pathophysiology, clinical features, and current management of tetanus are reviewed.

In spite of the World Health Organization's intention to eradicate tetanus by the year 1995, it remains endemic in the developing world. The WHO estimated that there were approximately 1,000,000 deaths from tetanus worldwide in 1992. This included 580,000 deaths from neonatal tetanus, of which 210,000 were in South East Asia and 152,000 in Africa. The disease is uncommon in developed countries. In South Africa approximately 300 cases occur each year (6 per million head of population), approximately 12-15 cases are reported each year in Britain (0.2 per million) and between 50 and 70 in the USA (0.2 per million).

Tetanus is caused by a Gram-positive bacillus, *Clostridium tetani*. This is a common bacterium with a natural habitat in the soil. It can also be isolated from animals and human faeces. It is a motile, spore-forming obligate anaerobe. The spore is incompletely destroyed by boiling but eliminated by autoclaving at 1 atmosphere pressure and 120°C for 15 min. It is rarely cultured, as the diagnosis of the disease is clinical. *Clostridium tetani* produces its clinical effects via a powerful exotoxin. The role of the toxin within the organism is not known. The DNA for this toxin is contained in a plasmid. Presence of the bacterium does not always mean that the disease will occur, as not all strains possess the plasmid. Bacterial antimicrobial sensitivity has been little investigated.

As infection does not confer immunity, prevention is through vaccination. Tetanus vaccine has been available since 1923. Vaccination is started at 2 months of age with three injections performed at monthly intervals. The second injection confers immunity with the third prolonging its duration. A booster is given before the age of 5. Similar responses occur in older children and adults. Neonatal immunity is provided by maternal vaccination and transplacental transfer of immunoglobulin. This may be impaired in the presence of maternal HIV infection. Immunity is not life-long. Revaccination at 10-yr intervals is recommended in the USA. In the UK, two boosters spaced 10 years apart are recommended in adulthood, so the recommendations do not extend to vaccination beyond the third decade. Thus in the UK, after the 5 injections patients are considered immune, and there is no value in giving further prophylactic doses. In the USA, more than 70% of cases and 80% of deaths occur in those over 50. Similar proportions are reported in Europe.

## PATHOPHYSIOLOGY

Under anaerobic conditions found in necrotic or infected tissue, the tetanus bacillus secretes two toxins: tetanospasmin and tetanolysin. Tetanolysin is capable of locally damaging viable tissue surrounding the infection and optimizing the conditions for bacterial multiplication.

### Toxins

Tetanospasmin leads to the clinical syndrome of tetanus. It binds to neural membranes and the amino terminus facilitates cell entry. It acts pre-synaptically to prevent neurotransmitter release from affected neurones. Released tetanospasmin spreads to underlying tissue and binds to gangliosides on the membranes of local nerve terminals. If toxin load is high, some may enter the bloodstream from where it diffuses to bind to nerve terminals throughout the body. The toxin is then internalized and transported intra-axonally and retrogradely to the cell body. Transport occurs first in motor and later in sensory and autonomic nerves. Once in the cell body the toxin can diffuse out, affecting and entering nearby neurones. When spinal inhibitory interneurons are affected, symptoms occur. Further retrograde intraneural transport occurs with toxin spreading to the brainstem and midbrain. This passage includes retrograde transfer across synaptic clefts by a mechanism that is unclear.

### Toxins and the CNS

The effects of the toxin result from prevention of neurotransmitter release. Synaptobrevin is a membrane protein necessary for the export of intracellular vesicles containing neurotransmitter. The tetanospasmin cleaves synaptobrevin, thereby preventing neurotransmitter release. The toxin has a predominant effect on inhibitory neurones, inhibiting release of glycine and gamma-aminobutyric acid (GABA). The term "disinhibition" is used as the main effect of tetanus. This results in a failure of inhibition (relaxation) of muscle groups leading to increased muscle tone and muscular spasms because the muscles are unable to relax. In normal muscles, when one muscle group contracts there has to be a corresponding relaxation of the opposing muscle group. In tetanus this is prevented and results in intermittent spasms. Interneurons inhibiting alpha motor neurones are first affected and the motor neurones lose inhibitory control. Later (because of the longer path), pre-ganglionic sympathetic neurones in the lateral horns and the parasympathetic centres are also affected. Motor neurones are similarly affected and the release of acetylcholine into the neuromuscular cleft is reduced. This effect is similar to the action of the closely related botulinum toxin, which produces a flaccid paralysis. However, in tetanus the disinhibitory effect on the motor neurone overwhelms any diminution of function at the neuromuscular junction. Medullary and hypothalamic centres may also be affected. Tetanospasmin has a cortical convulsant effect in animal studies. Whether these

mechanisms contribute to intermittent spasm and autonomic storms is unclear. The pre-junctional effect on the neuromuscular junction may lead to considerable weakness between spasms, and might account for both the paralysis of cranial nerves observed in cephalic tetanus, and myopathies observed after recovery.

Uncontrolled disinhibited efferent discharge from motor neurones in the spinal cord and brainstem leads to intense muscular rigidity and spasm, which may mimic convulsions. The reflex inhibition of antagonist muscle groups is lost, and agonist and antagonist muscles contract simultaneously. Muscle spasms are intensely painful and may lead to fractures and tendon rupture. Muscles of the jaw, face, and head are often involved first because of their shorter axonal pathways. The trunk and limbs follow but peripheral muscles in the hands and feet are relatively spared (Figure 1)

Disinhibited autonomic discharge leads to disturbances in autonomic control, with sympathetic overactivity and excessive plasma catecholamine levels. Neuronal binding of toxin is thought to be irreversible. Recovery requires the growth of new nerve terminals, which explains the prolonged duration of tetanus.

## CLINICAL FEATURES

Tetanus usually follows a recognized injury. Contamination of wounds with soil, manure, or rusty metal can lead to tetanus. It can complicate burns, ulcers, gangrene, necrotic snakebites, middle ear infections, septic abortions, childbirth, intramuscular injections, and surgery. Injuries may be trivial, and in up to 50% of cases the injury occurs indoors and/or is not considered serious enough to seek medical treatment. In 15-25% of patients, there is no evidence of a recent wound.

### Presentation

There is a clinical triad of rigidity, muscle spasms and autonomic dysfunction. Neck stiffness, sore throat, and difficulty opening the mouth are often early symptoms. Masseter spasm causes trismus or 'lockjaw'. Spasm progressively extend to the facial muscles causing the typical facial expression, 'risus sardonicus', and muscles of swallowing causing dysphagia (figure 1). Rigidity of the neck muscles leads to retraction of the head. Truncal rigidity may lead to opisthotonos, which is the severe arching of the back

Figure 1.

during a spasm caused by the stronger extensor muscle group. Respiratory difficulty with decreased chest wall compliance may also ensue.

In addition to increased muscle tone, there are episodic muscular spasms. These tonic contractions have a convulsion-like appearance affecting agonist and antagonist muscle groups together. They may be spontaneous or triggered by touch, visual, auditory or emotional stimuli. Spasms vary in severity and frequency, but may be strong enough to cause fractures and tendon avulsions. Spasms may be almost continual, leading to respiratory failure. Pharyngeal spasms are often followed by laryngeal spasms and are associated with aspiration and life-threatening acute airway obstruction.

Generalized tetanus, the commonest form of tetanus affects all muscles throughout the body. The muscles of the head and neck are usually affected first with progressive caudal spread of rigidity and spasm to affect the whole body. The differential diagnosis includes orofacial infection, dystonic drug reactions, hypocalcaemia, strychnine poisoning, and hysteria.

Local tetanus is seen with lower toxin loads and peripheral injuries. Spasm and rigidity are restricted to a limited area of the body. Mortality is greatly reduced. An exception to this is cephalic tetanus when localized tetanus from a head wound affects the cranial nerves; paralysis rather than spasm predominates at presentation (figure 2) but progression to generalized tetanus is common and mortality is high.

Tetanus neonatorum causes more than 50% of deaths from tetanus worldwide but is very rare in developed countries. Neonates present within a week of birth with a short history of failure to feed, vomiting, and 'convulsions'. Seizures, meningitis, and sepsis are differential diagnoses. Spasms are generalized and mortality is high. Poor umbilical hygiene is the cause of the disease but it is entirely preventable by maternal vaccination, even during pregnancy.

### Autonomic effects

Prior to the introduction of artificial ventilation, many patients with severe tetanus died from acute respiratory failure. With the development of intensive care and the ability to ventilate patients it became apparent that severe tetanus was associated with marked autonomic instability. The sympathetic nervous system is most prominently affected. Clinically, increased sympathetic tone causes persistent tachycardia and hypertension. Marked vasoconstriction and pyrexia are also seen. Basal plasma catecholamine levels are raised. 'Autonomic storms' occur with marked cardiovascular instability. Severe hypertension and tachycardia may alternate with profound hypotension, bradycardia, or recurrent cardiac arrest. These alterations are a result of rapid alterations in systemic vascular resistance, rather than problems with cardiac filling or performance. During these 'storms' plasma catecholamine levels are raised up to 10-fold, to levels similar to those seen in phaeochromocytoma. Norepinephrine (noradrenaline) is affected more than epinephrine (adrenaline). Neuronal hyperactivity rather than adrenal medullary hyperactivity appears to predominate.

Figure 2

In addition to the cardiovascular system, other autonomic effects include profuse salivation and increased bronchial secretions. Gastric stasis, ileus, diarrhoea, and high output renal failure may all be related to autonomic disturbance.

The involvement of the sympathetic nervous system is established. The role of the parasympathetic system is less clear. Tetanus has been reported to induce lesions in the vagal nuclei, while locally applied toxin may lead to excessive vagal activity. Hypotension, bradycardia, and asystole may arise from increased vagal tone and activity.

#### Natural history

The incubation period (time from injury to first symptom) averages 7-10 days, with a range of 1-60 days. The onset time (time from first symptom to first spasm) varies between 1-7 days. Shorter incubation and onset times are associated with more severe disease. The first week of the illness is characterized by muscle rigidity and spasms, which progressively increase in severity. Autonomic disturbance usually starts several days after the spasms, and persists for 1-2 weeks. Spasms reduce after 2-3 weeks, but stiffness may persist considerably longer. Recovery from the illness occurs because of re-growth of axon terminals and by toxin destruction.

#### SEVERITY GRADING

There are several grading systems but the system reported by Ablett is most widely used (table 1).

#### Altered cardiovascular physiology

In uncomplicated tetanus, the cardiovascular system mimics that of a normal patient undergoing intense exercise. There is a hyperdynamic circulation largely because of increased basal

Table 1: Ablett classification of tetanus severity

Grade	Clinical Features
1	Mild: mild trismus, general spasticity, no respiratory embarrassment, no spasms, no dysphagia.
2	Moderate: moderate trismus, rigidity, short spasms, mild dysphagia, moderate respiratory involvement, respiratory rate > 30, mild dysphagia.
3	Severe: Severe trismus, generalized spasticity, prolonged spasms, respiratory rate > 40, severe dysphagia, apnoeic spells, pulse > 120.
4	Very severe: grade 3 with severe autonomic disturbances involving the cardiovascular system.

sympathetic activity and muscle metabolism, with a lesser effect from raised core temperature. There is low-normal systemic vascular resistance and raised cardiac output, because of extensive vasodilatation in metabolically active muscles. As the oxygen extraction ratio does not alter in tetanus, the increased demand must be delivered by increased blood flow. Poor spasm control exaggerates these effects. In severe tetanus, patients are less able to increase cardiac performance and are more susceptible to profound hypotension and shock during acute vasodilatory storms. The mechanism is unclear but may relate to sudden reduction of catecholamine secretion or a direct action of tetanus toxin on the myocardium. Altered myocardial function may occur due to persistently raised catecholamine levels, but abnormal function may occur even in the absence of sepsis or high catecholamine levels.

#### Altered respiratory physiology

Muscular rigidity and spasms of the chest wall, diaphragm, and abdomen lead to a restrictive defect. Pharyngeal and laryngeal spasms predict respiratory failure or life-threatening airway obstruction. Poor cough from rigidity, spasms, and sedation leads to atelectasis and the risk of pneumonia is high. The inability to swallow copious saliva, profuse bronchial secretions, pharyngeal spasms, raised intra-abdominal pressure, and gastric stasis all increase the risk of aspiration, which is common. Ventilation/perfusion mismatch is also common. Consequently, hypoxia is a uniform finding in moderate or severe tetanus even when the chest is radiologically clear. When breathing air, oxygen tensions are often between 5.3-6.7kPa (40-50mmHg), with the oxygen saturation commonly falling below 80%. In artificially ventilated patients, increased A-a gradients persist. Oxygen delivery and utilization may be compromised even without super-added lung pathology. Acute respiratory distress syndrome may occur as a specific complication of tetanus. Minute ventilation may be altered by a variety of causes. Hyperventilation may occur because of fear, autonomic disturbance, or alteration in brainstem function. Hypocarbia (PaCO<sub>2</sub> 4.0-4.6 kPa (30-35mmHg)) is usual in mild to moderate disease. Hyperventilation 'storms' may lead to severe hypocarbia (PaCO<sub>2</sub> <3.3 kPa (25mmHg)). In severe disease, hypoventilation from prolonged spasms and apnoea occurs. Sedation, exhaustion and altered brainstem function may also lead to respiratory failure. Respiratory drive may be deficient

leading to recurrent life-threatening apnoeic periods.

**Altered renal physiology**

In mild tetanus, renal function is preserved. In severe disease reduced, glomerular filtration rate and impaired renal tubular function are frequent. Contributory causes of renal failure include dehydration, sepsis, blocking of the renal tubule with myoglobin (as a result of muscle breakdown), and alterations in renal blood flow secondary to catecholamine surges. Renal failure may be oliguric or polyuric. Clinically important renal impairment is associated with autonomic instability and histology is normal or shows acute tubular necrosis.

ADULT TETANUS PROTOCOL
St.Mary's Hospital Lacor Gulu, Uganda
<ol style="list-style-type: none"> <li>1. Start metronidazole intravenously 500mg three times a day.</li> <li>2. Give tetanus human immune globulin IM 3,000-6,000 iu if available. If not available Equine ATS 10,000 iu IM.</li> <li>3. Admit ICU, commence oxygen, IV access and monitoring.</li> <li>4. Alert surgeon to do radical debridement. Nasogastric tube may be passed during surgery.</li> <li>5. Slow loading dose diazepam IV to control spasms. Up to about 40mg may be required. Give a loading dose of 5g magnesium sulphate slowly over 20 minutes IV.</li> <li>6. Start diazepam 10mg 6 hourly and increase to hourly if required. Titrate to symptoms.</li> <li>7. Start magnesium 2.5g IV 2 hourly and increase to hourly if required. Titrate to symptoms. Stop diazepam if symptoms controlled by magnesium alone.</li> <li>8. Phenobarbitone up to 200mg IV twice a day for breakthrough spasms using 50mg doses.</li> <li>9. Tracheostomy if airway compromised by above treatment.</li> <li>10. Intermittent positive pressure ventilation with muscle relaxants if respiration compromised by treatment or uncontrolled spasms.</li> </ol>

**MANAGEMENT**

Treatment strategies involve three management principles:

- Organisms present in the body should be destroyed to prevent further toxin release
- Toxin present in the body, outside the CNS should be neutralized and
- The effects of toxin already in the CNS should be minimized.

**Removal of the source of infection**

Where present, obvious wounds should be surgically debrided. The surgeon should be encouraged to perform a radical

debridement to eliminate as much of the source of infection as possible. Penicillin has been widely used for many years but is a GABA antagonist and is associated with convulsions. Metronidazole is probably the antibiotic of choice. It is safe and comparative studies with penicillin suggest at least as good results. Erythromycin, tetracycline, chloramphenicol, and clindamycin are all accepted as alternatives.

**Neutralization of unbound toxin**

If available human tetanus immune globulin 3000-6000 units is given intra-muscularly (IM). If this is not available (which is often the case in the developing world), then anti-tetanus horse serum (ATS) should be given after sensitivity tests, in a dose of 10,000 units IM. All these injections should be administered within 24 hours of the diagnosis.

**Control of rigidity and spasms**

The principle of management is to prevent spasms and rigidity with the minimal dose of pharmacological agent, so that the side effects of the drugs themselves do not become life-threatening. Obtaining the correct dose of agent cannot be judged without frequent assessment by the clinician especially in the early stages. Clinical symptoms may change rapidly.

Avoidance of unnecessary stimulation is mandatory, but the mainstay of treatment is sedation with a benzodiazepine. Benzodiazepines increase GABA activity, by inhibiting an endogenous inhibitor at the GABA<sub>A</sub> receptor. Diazepam may be given by various routes. It is cheap and widely used, but long acting metabolites (oxazepam and desmethyldiazepam) may accumulate and lead to prolonged coma. Doses will vary with individuals but a starting dose of 10mg every 6 hours is usual. Higher doses of 20 or 40mg 6 hourly may be necessary. Midazolam has been used with less apparent cumulation.

Additional sedation may be provided by anticonvulsants, particularly phenobarbitone at a dose of up to 200mg IV twice a day. Phenobarbitone has a GABA agonist effect. However it is a potent respiratory depressant and should be used with caution, starting with low doses of 50mg twice a day.

Phenothiazines, usually chlorpromazine have often been used. However caution is essential to avoid deep depression of protective reflexes and the risk of pulmonary aspiration.

In situations where full intensive care facilities are available, the classical teaching is to proceed to tracheostomy and IPPV when sedation does not control the spasms, or when the necessary doses of sedative produce such deep depression of the airway reflexes or respiration that the patient is no longer safe. However, in many parts of the developing world there is little capacity to perform a tracheostomy or give IPPV. Even if a surgeon is available to perform a tracheostomy, the nursing care demands of a tracheostomy over several weeks puts a major strain on nursing capacity, and is frequently not undertaken without firstly considering other treatment options.

Magnesium sulphate may offer some new hope in this context. In Sri Lanka, Attygalle and Rodrigo<sup>2</sup> reported a series of 40 patients with tracheostomy in which IPPV was avoided by using magnesium sulphate. There has also been a report from the USA

where the need for tracheostomy was avoided through the use of magnesium sulphate<sup>3</sup>. The dose suggested is 1g increasing to 2.5g per hour in the adult following a 5g loading dose. The therapeutic serum magnesium levels were 2–4mmols per litre (normal 1.2mmol per litre). Magnesium is a pre-synaptic neuromuscular blocker. It blocks catecholamine release from nerves and the adrenal medulla. It also reduces receptor responsiveness to released catecholamines, is an anticonvulsant and a vasodilator. It antagonises calcium in the myocardium and at the neuromuscular junction, and inhibits parathyroid hormone release lowering serum calcium. If too large a dose is given, it causes weakness and paralysis with central sedation (although the latter is controversial). Attygalle advises using the presence of patella tendon reflexes as a monitor of a safe serum magnesium level. Hypotension and bradyarrhythmia may occur. It is therefore mandatory to maintain magnesium levels in the therapeutic range. In a report by James and Manson<sup>4</sup>, patients with very severe tetanus were studied. In these patients, magnesium was found to be inadequate alone as a sedative and relaxant, but was an effective adjunct in controlling autonomic disturbance. The author's experience of using magnesium to manage severe tetanus in rural Africa has been positive, with good outcomes. The future place of magnesium will require further studies but it offers hopeful new possibilities

Neuromuscular blocking agents and intermittent positive pressure ventilation may be required for a prolonged period when sedation alone is inadequate. Traditionally, the long acting agent pancuronium has been used and it is cheaper than the more modern non-depolarising muscle relaxants. Vecuronium, atracurium and rocuronium have also been used.

Propofol sedation has allowed control of spasms and rigidity without the use of neuromuscular blocking drugs. However, drug levels were closer to anaesthetic than sedative concentrations and mechanical ventilation would be required.

### Control of autonomic dysfunction

Many different approaches to the treatment of autonomic dysfunction have been reported. Most are presented as case reports or small case series. There is a lack of comparative or controlled studies. In general, outcome measures have been limited to haemodynamic data, rather than survival or morbidity.

Sedation is often the first treatment. Benzodiazepines, anticonvulsants, and morphine are frequently used. Morphine is particularly beneficial as cardiovascular stability may be achieved without cardiac compromise. Dosages vary between 20 and 180 mg daily. Proposed mechanisms of action include replacement of endogenous opioids, reduction in reflex sympathetic activity and release of histamine. Phenothiazines, particularly chlorpromazine are also used; anticholinergic and -adrenergic antagonism may contribute to cardiovascular stability.

$\alpha$ -adrenergic blocking agents, such as propranolol, were used in the past to control episodes of hypertension and tachycardia, but profound hypotension, severe pulmonary oedema and sudden death were all found to occur. Labetolol, which has combined  $\alpha$  and  $\beta$  adrenergic blocking effects has been used, but no advantage over propranolol was demonstrated (possibly because its  $\alpha$  activity is much less than its  $\beta$  activity), and mortality remained

high. In recent years, the short-acting agent, esmolol, has been used successfully. Although good cardiovascular stability was achieved, arterial catecholamine concentrations remained elevated.

Sudden cardiac death is a feature of severe tetanus. The cause remains unclear but plausible explanations include sudden loss of sympathetic drive, catecholamine-induced cardiac damage and increased parasympathetic tone or 'storms'. Persisting beta blockade could exacerbate these causes because of its negatively inotropic effect or vasoconstrictor activity. This may lead to acute cardiac failure, particularly as sympathetic crises are associated with high systemic vascular resistance and normal or low cardiac output. Isolated use of  $\alpha$ -adrenergic block with long acting agents cannot therefore be recommended.

Postganglionic and -adrenergic blocking agents such as bethanidine, guanethidine, and phentolamine have been successfully used with propranolol, along with other similar agents such as trimetaphan, phenoxybenzamine, and reserpine. Disadvantages of this group of drugs are that induced hypotension may be difficult to reverse, tachyphylaxis occurs and withdrawal can lead to rebound hypertension.

The  $\alpha$ -adrenergic agonist clonidine has been used orally or parenterally, with variable success. Acting centrally, it reduces sympathetic outflow, thus, reducing arterial pressure, heart rate, and catecholamine release from the adrenal medulla. Peripherally, it inhibits the release of norepinephrine from pre-junctional nerve endings. Other useful effects include sedation and anxiolysis.

Magnesium sulphate has been used both in artificially ventilated patients to reduce autonomic disturbance and in non-ventilated patients to control spasms. The dose suggested is 1g increasing to 2.5g per hour for an adult.

### Supportive intensive care treatment

Weight loss is universal in tetanus. Contributory factors include inability to swallow, autonomic induced alterations in gastrointestinal function, increased metabolic rate (due to pyrexia and muscular activity), and prolonged critical illness. Nutrition should therefore be established as early as possible. Enteral nutrition is associated with a lower incidence of complications and is cheaper than parenteral nutrition. Nasogastric tube feeding should be started as soon as possible. In experienced units, percutaneous gastrostomy may be more suitable as a route for feeding.

Infective complications of prolonged critical illness, including ventilator-associated pneumonia, are common in tetanus. Securing the airway early in the disease and preventing aspiration and sepsis are logical steps in minimizing this risk. As artificial ventilation is often necessary for several weeks tracheostomy is usually performed after intubation. In experienced hands the percutaneous dilatational method may be particularly suitable for patients with tetanus. This bedside procedure avoids transfer to and from the operating theatre with the attendant risk of provoking autonomic instability. Prevention of respiratory complications also involves meticulous mouth care, chest physiotherapy, and regular tracheal suction, particularly as salivation and bronchial secretions are greatly increased.

Adequate sedation is mandatory before such interventions in patients at risk of uncontrolled spasms or autonomic disturbance. The balance between physiotherapy and sedation may be difficult to achieve.

Other important measures in the routine management of patients with tetanus (as with any long-term critical illness), include prophylaxis of thromboembolism, gastro-intestinal haemorrhage, and pressure sores. The importance of psychological support should not be underestimated.

Venous access is a major problem when diazepam has been used for many days using peripheral veins. An elective placement of a central or femoral line improves general care and outcomes.

### COMPLICATIONS

Complications may occur as a result of the disease (e.g. laryngospasm, hypoxia), or as a consequence of treatment (e.g. sedation leading to coma, aspiration or apnoea; ventilator-associated pneumonia; complications of tracheostomy; acute respiratory distress syndrome). Gastro-intestinal complications include gastric stasis, ileus, diarrhoea and haemorrhage. Cardiovascular complications include tachycardia, bradycardia, hypertension, hypotension and asystole. High output renal failure and oliguric renal failure are reported and thromboembolism and overwhelming sepsis also occur.

### MORTALITY AND OUTCOME

Fatality rates and causes of death vary dramatically according to the facilities available. Without doubt the introduction of intensive care treatment will reduce mortality. In developing countries, without facilities for prolonged intensive care and ventilatory support, deaths from severe tetanus exceed 50% with airway obstruction, respiratory failure, and renal failure as prominent causes. A mortality of 10% has been suggested as an acceptable goal in developed countries. Modern intensive care should prevent death from acute respiratory failure, but as a result, in severe cases, autonomic disturbance becomes more apparent. Before ICU care was established about 80% of patients died as a result of early acute respiratory failure. Important complications of ICU care include nosocomial infections (particularly ventilator-

associated pneumonia), generalized sepsis, thromboembolism, and gastrointestinal haemorrhage. Mortality varies with patient age. In the USA, mortality in adults below 30yr may approach zero, but in those over 60yr is 52%. In Africa, mortality from neonatal tetanus without artificial ventilation is over 80%.

Severe cases of tetanus generally require ICU admission for approximately 3-5 weeks. Recovery can be expected to be complete, with return to normal function, although some survivors of tetanus may have persistent physical and psychological problems.

### CONCLUSION

Tetanus is entirely preventable by vaccination. However it remains a major health problem worldwide. In developed countries, several cases present every year in the elderly and unimmunised population. Mortality in these cases remains high. Prolonged intensive care support may be necessary but most treatment is based on limited evidence. Major therapeutic challenges lie in the control of muscular rigidity and spasms, the treatment of autonomic disturbance and the prevention of complications associated with prolonged critical illness. For the developing world tetanus is a major challenge with a high mortality among all age groups. The use of magnesium to avoid long term ventilation is a hopeful development that will need further evaluation. Return to normal function can be expected in those who survive.
