Morphine can be given into the epidural or subarachnoid space. This is to deliver the morphine close to one of its sites of action, the spinal cord. It is thought that pain relief of long duration can be obtained with very low doses of morphine. A single dose of epidural morphine may relieve pain for 12-24 hours. The usual adult dose for epidural morphine is 3-7 milligrams, and of subarachnoid morphine between 250mcg and 1mg. The main risk of this technique is that severe respiratory depression may occur up to 18 hours after the initial injection because of the slow circulation of cerebral spinal fluid which carries the morphine up to the brain to act on the respiratory centre. It is vital that all those caring for a patient who has had this technique are aware of the potential side effects and watch out for them. This technique can only be used in specialist hospitals with intensive care facilities. In all other aspects the side effects of epidural and subarachnoid morphine are similar to morphine given by any other route.

**CLINICAL DILEMMA**

A 26 year old man was admitted to your hospital after a road traffic accident. He had abdominal pain and was found to be breathless and cyanosed on examination. His chest X ray is seen in figure 1.

1. What is the abnormality seen?
2. What complications may occur with it?
3. What is the treatment?

**Answers**

1. The X ray shows a traumatic rupture of the left diaphragm with bowel in the chest.
2. The bowel may herniate through the tear as is seen in the X ray. If gastric dilation develops severe respiratory distress may result. If treatment of the herniation is delayed ischaemia may develop in the affected bowel leading to gangrene.
3. Many cases of ruptured diaphragm are associated with other intra-abdominal injuries and it is usually repaired at the same laparotomy.

Treatment should include oxygenation, resuscitation and in the presence of a lot of gastric air the passage of a nasogastric tube. During anaesthesia ventilation should be controlled due to the inefficient ventilation resulting from this injury.

**Comment.**

Traumatic diaphragmatic hernias are more often described on the left than the right. They are usually the result of severe blunt trauma which causes a tear in the dome of the diaphragm resulting in herniation. Since the intra-abdominal pressure is higher then, the pleural pressure bowel will tend to move into the thoracic cavity.

There is often a delay in diagnosis until breathlessness results from gastric dilation. Clinically the patient may have reduced air entry on the effected side, and bowel sounds may be audible in the left chest. A chest X ray may reveal the characteristic changes seen in the example, or may be misdiagnosed as Penetrating trauma may also cause lacerations of the diaphragm which are usually small. Herniation is less common at the time of injury, but the patient may present years later when a hernia develops.
showing other changes at the left base such as pleural fluid or basal consolidation. If the stomach is dilated the X ray may suggest a pneumothorax, which if drained would reveal gastric contents. If a nasogastric tube has been passed it may be seen in the chest on X ray. The condition is also sometimes diagnosed at laparotomy performed for other abdominal injuries. In cases of doubt a chest X ray taken after ingestion of contrast material will confirm the diagnosis. After diagnosis, treatment should not be delayed due to the potential complications discussed earlier. The left diaphragm is usually repaired at laparotomy, right sided injuries (which are uncommon and may be difficult to diagnose) via a thoracotomy.

THE MAINTENANCE OF AN ANEROID SPHYGMOMANOMETER
Mr Mike Yeats, Derriford Hospital, Plymouth

The first article in this series described the maintenance of a mercury sphygmomanometer, this article describes the maintenance of an aneroid blood pressure apparatus. Aneroid means, in Greek, operating without liquid or containing no fluid. Aneroid blood pressure gauges are generally smaller than mercury ones but they are easily damaged and can go out of calibration without detection.

A common type of aneroid apparatus is shown in figure 1. It consists of a dial which normally rises to 300mmHg and a thin brass corrugated bellows inside. There is a shaft which connects two pins at right angles to each other; one of these rests on the bellows, the other is inside a concave sided triangle which meshes with a pinion connected to the dial pointer. A thin coiled spring (known as a hair spring) is also connected to the pinion and returns the pointer to zero when the pressure is released.
